The reliability and validity of the Timed Up and Go as a clinical tool in individuals with and without disabilities across a lifespan: a systematic review

Psychometric properties of the Timed Up and Go

Ashley Christopher, Emily Kraft, Hannah Olenick, Riley Kiesling and Antonette Doty

Physical Therapy Department, Walsh University, North Canton, OH, USA

ABSTRACT

Purpose: To summarize the available literature related to reliability and validity of the Timed Up and Go in typical adults and children, and individuals diagnosed with the following pathologies: Huntington's disease, stroke, multiple sclerosis, Parkinson's disease, spinal cord injury, Down syndrome, or cerebral palsy.

Materials and methods: A search was conducted using MeSH terms and keywords through a variety of databases. Data regarding reliability and validity were synthesized.

Results: This review included 77 articles. Results were variable depending on the studied population. The Timed Up and Go showed excellent reliability in typical adults, in individuals with cerebral palsy, in individuals with multiple sclerosis, in individuals with Huntington's disease, individuals with a stroke, and individuals with a spinal cord injury. The TUG demonstrated strong concurrent validity for individuals with stroke and spinal cord injury. Predictive validity data was limited.

Conclusions: Based on the literature assessed, the Timed Up and Go is clinically applicable and reliable across multiple populations. The Timed Up and Go has a wide variety of clinical use making it a diverse measure that should be considered when choosing an outcome an activity based outcome measure. However, there are some limitations in the validity of the utilization of the Timed Up and Go to some populations due to a lack of data and/or poor choice of comparison outcome measures when assessing validity. Additional research is needed for young to middle aged adults.

developmental disabilities

► IMPLICATIONS FOR REHABILITATION

- Outcome measures are a vital component of clinical practice across all populations.
- The Timed Up and Go is a highly studied outcome measure in the geriatric population, but lacks research of its applicability to other populations.
- This study was able to highlight the clinical utility of the Timed Up and Go in populations that under utilize this outcome measure.

Introduction

There are over 400 outcome measures used in physical therapy, creating challenges for therapists when choosing the appropriate measure for patients [1]. Many people with and without disabilities experience difficulty with mobility and functional activities throughout their lifespan. These difficulties with mobility and functional activities need to be quantified in order to assess patients' success with therapy.

Outcome measures are designed to measure patient strengths and limitations, provide measurement of functions, predict future outcomes, and direct interventions for patients plan of care over time [2]. Measures may be structured as self-reports or performance-based measures, and may be disease specific or applied to the general population [3]. In order to obtain a full evaluation of patient function, multiple outcome measures should be utilized, targeting the different dimensions of the International Classification of Functioning, Disability, and Health (ICF) model [3,4]. In addition, clinicians must choose outcome measures based on strong psychometric properties.

The ICF, proposed as a framework for patient management, defines an individual by his or her participation roles rather than disease or illness. This model illustrates the interplay between health condition, community activities, and contextual factors to optimize patient function and participation within their own environment. It proposes a shift from solely treating impairments to a focus on increasing participation in life roles that are meaningful to the patient [4]. Figure 1 is an illustration of the ICF applied to a community dwelling geriatric patient.

The Timed Up and Go (TUG) is a commonly used outcome measure that can assess activity limitations in the ICF model by examining the patient's ability to ambulate and perform transfers. If a patient has a deficit in these activities, it may impact life participation if they are unable to participate in their societal roles. The TUG was originally created to predict fall risk in geriatric patients [5]. The focus of the test has been shown to be a relevant outcome measure when assessing balance and general mobility for patients with various disabilities across the lifespan. The psychometric properties of the TUG have been examined individually through clinical studies in the following populations: stroke [6],

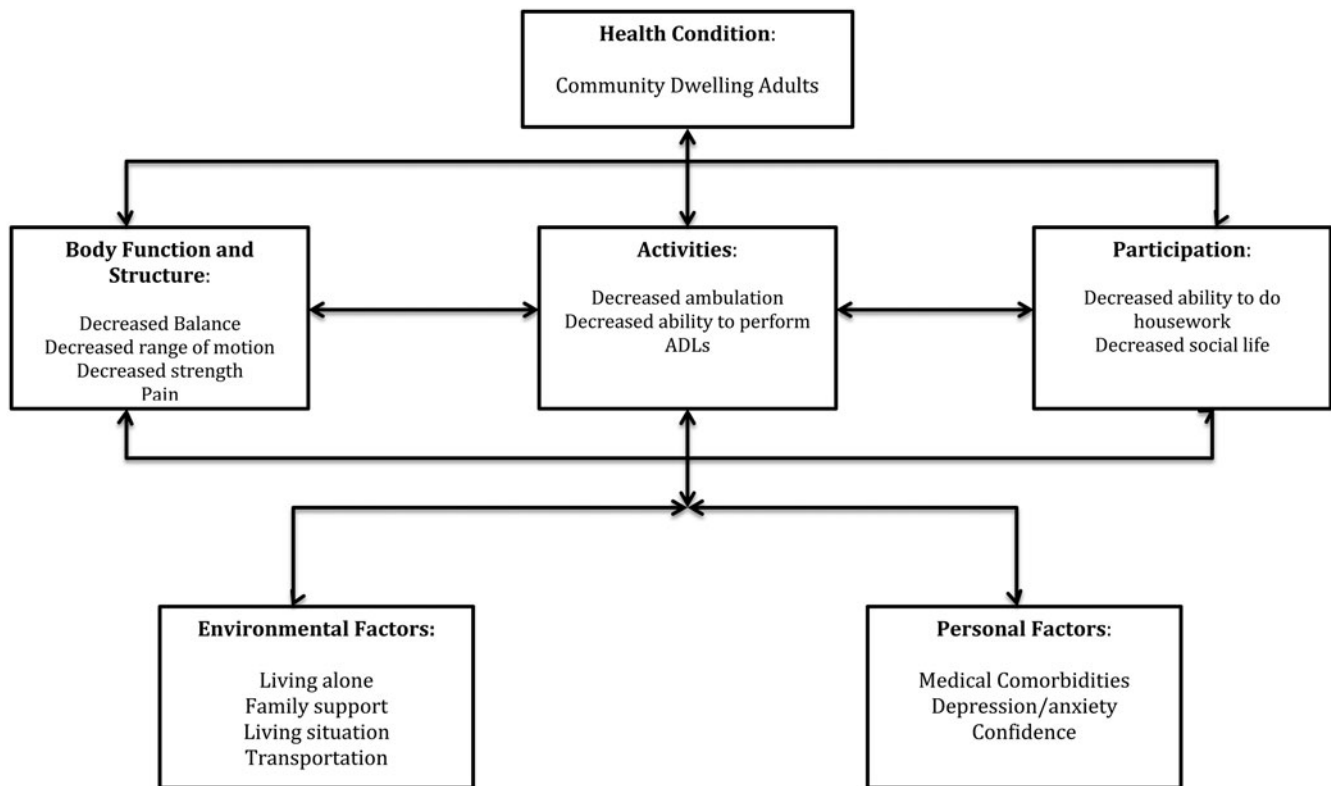

Figure 1. ICF Model applied to aging community dwelling adults.

cerebral palsy (CP) [7], Parkinson's disease (PD) [8], and spinal cord injury (SCI) [9].

A single evidence-based resource dedicated to the reliability and validity of the TUG across prevalent populations would streamline the decision-making process for clinicians. Inter-population comparisons illustrate the clinical utility of the TUG in a variety of clinical settings. Finally, providing an inclusive resource will highlight the necessity for further research in additional populations.

Since previous reviews only analyzed singular populations, the purpose of the current review is to assemble the current literature available and synthesize the clinical utility, reliability, and validity in a variety of populations including: (1) individuals with the adult diagnoses of Huntington's disease (HD), individuals with multiple sclerosis (MS), individuals with PD, individuals with SCI, individuals with a stroke; (2) pediatric patients with the diagnoses of Down syndrome (DS) and CP; and (3) typical adults and children.

Methods

This systematic review has been registered through PROSPERO, which combines prospectively registered systematic reviews into an international database. The aim of PROSPERO is to ensure that there are no duplications of systematic reviews [10]. The PROSPERO registration number associated with this systematic review is CRD42018085354. The systematic review also followed the *Preferred Reporting Items for Systematic Reviews and Meta-Analysis* (PRISMA) guidelines for publication, which is a checklist that insures consistency and quality of methodology behind systematic reviews [11].

Eligibility criteria

Populations available for inclusion examined neurological or developmental pathologies. Studies included are scholarly,

peer-reviewed articles investigating the reliability and validity of the TUG. Studies were excluded if they were not published in English, did not examine neurological or developmental pathologies, and solely discussed responsiveness. Modified versions of the TUG were excluded, apart from the modified version for children, due to the preservation of measurement criteria and task conditions. The adaptations to the TUG for children were focused on altering the directions, yet kept the underlying methodology the same. This was done to ensure clear understanding for the child-based population.

Search strategy

Four electronic databases were searched (PUBMED, CINAHL, ProQuest, and Scopus) to locate applicable content. An example of the search strategy implemented with PUBMED is included in [Supplemental Material](#). The original search concepts were age, disability, the TUG, and psychometric properties. The age concept was divided into the subgroups of child, adult, and elderly. The use of these subgroups and MeSH terms were determined to be the optimal way to ensure a complete search of the lifespan [12]. Following database searches, a hand search was performed of systematic reviews addressing the psychometric properties of the TUG to acquire additional articles that fit the criteria. A grey literature search was also completed in databases including Google Scholar, PROSPERO, Center Watch, and Grey Literature Report. The date of the last complete search was January of 2018.

Study selection

Following the initial search, all the articles found between databases were combined and duplicates were removed. Two reviewers then screened titles and abstracts for possible inclusion criteria. All discrepancies were discussed between the reviewers

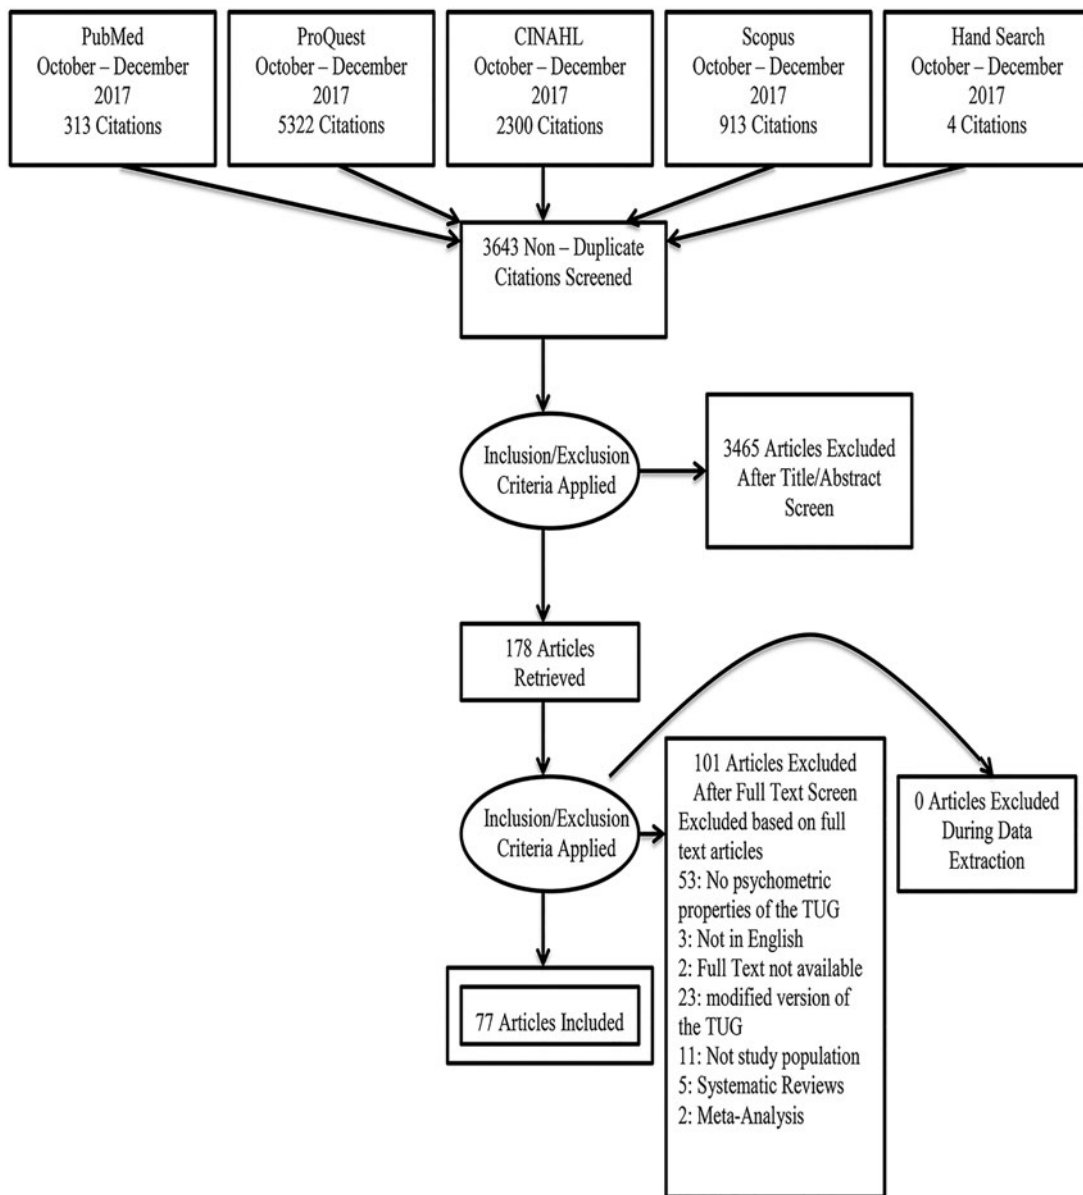

Figure 2. PRISMA flow diagram.

and a final decision was agreed upon. Two different reviewers screened the remaining full text articles. Disagreements were discussed, and a final decision was made through consensus between the two reviewers. Cohen's unweighted kappa values were calculated for each step of the screening process to quantify interrater reliability between reviewers [13]. The reference scale used for calculated kappa scores is as follows: a kappa score less than 0.00 is considered poor, 0.00–0.20 is considered slight, 0.21–0.40 is considered fair, 0.41–0.60 is considered moderate, 0.61–0.80 is considered substantial, and 0.81–1.00 is considered almost perfect [14].

Risk of bias in included studies

The McGill Mixed Methods Assessment Tool (MMAT) was used to assess the quality of the included studies [15]. This tool is applicable to a variety of study designs including qualitative, quantitative randomized control trials, quantitative non-randomized, quantitative descriptive, and mixed methods [15]. The MMAT has two screening questions for every included study followed by a

category dictated by the study design. Each question is given the response of "Yes", "No", or "Can't tell." Dependent upon the category of the MMAT used, there are three to four questions to answer and score based on the percentage of questions answered yes. Scores will range from 0% (0/4 yes) to 100% (4/4 yes). Studies that scored 100% demonstrate least risk of bias as determined by sound methodology. The reliability and validity of the MMAT pilot study has been tested and determined to be adequate [15]. The risk of bias was first independently assessed by two reviewers; following individual assessment, the reviewers compared scoring and discussed any discrepancies to create a final score for each article. Kappa was calculated based on the agreement of the two individual reviewers.

Outcomes/summary measures

The outcomes of this study examined the reliability and validity of the TUG. The TUG is an outcome measure that is used to assess functional mobility in a variety of populations. The TUG is performed by having the patient seated in a chair and with the

Table 1. Study characteristics.

command “go”, rise from the chair, walk 3 meters, turn around, return to chair and sit. The trial is timed from when the patient's back leaves the backrest to when the patient returns to the seated position, and the patient is allowed one practice trial [5]. A shorter time represents better mobility [5]. The review looked at the reliability and validity of this outcome measure within each subgroup of the populations discussed.

Reliability measures how consistently and free from error an outcome measure captures results [16]. The sub-types of reliability that were used for the systematic review include test-retest, inter-rater, and intra-rater. Test-retest reliability examines reliability of a test between test trials. Inter-rater reliability is how reliable an outcome measure is between different test administrators, while intra-rater reliability demonstrates how reliable an outcome measure is when the same administrator conducts a test multiple times [16]. Intraclass correlation coefficient (ICC) measures reliability. Values less than 0.5 were considered to be poor, between 0.5 and 0.75 indicated moderate, values between 0.75 and 0.9 indicated good, and values larger than 0.9 were determined to be excellent [17].

Validity is defined by ability of a measure to capture the intended data [16]. The types of validity included were concurrent and predictive. Concurrent validity is the extent to which two measurements agree when measuring the same construct as represented by Spearman Rho (ρ) and Pearson (r) [16,18]. The following scale was used to determine the strength of r values: greater than or equal to 0.60 was considered a strong correlation, 0.30–0.59 was a moderate correlation, and less than 0.30 was a

weak correlation [19]. Predictive validity measures whether a finding was a predictor of a future outcome and is reported by area under the curve and odds ratio [20].

Data extraction

The reviewers extracted data regarding reliability and validity of the TUG across multiple ages and populations, as well as the demographics of participants utilizing the TUG. When available, the clinical use of the TUG and normative data were obtained from the articles. Two reviewers performed the data extraction. Both reviewers extracted data from the included articles and then data was cross-checked for accuracy.

Results

Study selection

The results of the search strategy produced 8848 articles, duplicates were removed to produce 3643 articles. Titles and abstracts were screened together to produce 178 articles to be reviewed for full text screen, with a kappa value of 0.59 (CI 95%, 0.53–0.66: moderate agreement) [13,14]. Upon completion of the full text screen, 77 articles were included in this systematic review, with a kappa value of 0.28 (CI 95%, 0.13–0.44: fair agreement) [13,14]. A hand search through relevant, previously published systematic reviews provided four additional articles that fit the inclusion criteria. The grey literature search did not produce any relevant

Y: Yes; N: No; C: Can't tell.

Screening Questions: 1. Are there clear qualitative and quantitative research questions (or objectives), or a clear mixed methods question (or objective)? 2. Do the collected data allow address the research question (objective)? Category 4: Quantitative descriptive: 4.1. Is the sampling strategy relevant to address the quantitative representative of the population under study? 4.2. Is the sample representative of the population under study? 4.3. Are measurements appropriate (clear origin, or validity known, or standard instrument)? 4.4. Is there an acceptable response rate (60% of above)?

prepublications. The PRISMA flow diagram with detailed explanation of the selection process is presented in Figure 2.

Study characteristics

The study designs of the included full text articles were cross-sectional, quantitative-descriptive. The sample size in each study ranged from 6 to 2854, with the ages ranging from 3 to 94 years old. Studies examining a specific disease or disability were noted; otherwise, the study population was noted to be “without disability”, “healthy”, or “typical”. Specific study characteristic data can be referenced in Table 1.

Risk of bias in included studies

The MMAT quality assessment scores can be viewed in Table 2. Most studies score a 75%-100% on the MMAT, with only six falling below 75%. This means that a majority of the studies had a low risk of bias. Many studies proved to be methodologically sound; however, a commonly missed criterion was acceptable response rate (question 4.4). The response rate was not able to be calculated because many studies failed to report the number of individuals originally recruited or the number of patients who completed the test-retest portion of the study. Another commonly missed criterion, was not reporting the source of the study sample (question 4.1). The kappa calculated for the agreement between reviewers for quality assessment was 0.56 (CI 95%, 0.38–0.73: moderate) [13,14].

Results of individual studies

Reliability

Reliability was divided based on test-retest, inter-rater and intra rater reliability. Reliability for all included studies can be found in Table 3. A majority of populations reported excellent test-retest reliability. The populations that support this include: pediatric individuals with CP [28,32,45,51,80], individuals with HD [76], individuals with a stroke[30,49,68,69], typical adults [65,70,85] and individuals with MS [62,72,95]. A range of test-retest reliability was found for the remainder of the populations that assessed test-retest reliability. Moderate to excellent values were reported for typical children [71,94]. Moderate to good values were reported for individuals with PD [35,50,85]. Good to excellent test-retest reliability was reported for pediatric individuals with DS

[66,71] in two studies; however, one study reported poor values for this population [93].

Intra-rater reliability reported as excellent in individuals that were diagnosed with CP [94], PD [67,92], and SCI [91], as well as typical adults [5,34,84]. Individuals with a stroke [40,64] and typical children [56,71,94] reported intra-rater reliability as a range of good to excellent when assessed. Inter-rater reliability was found to be excellent when studied in individuals with PD [92], individuals with SCI [75,91], individuals with a stroke [40,41,64], typical adults [5,34,82] and individuals with MS [95].

Validity

Validity was divided into two subgroups: concurrent and predictive. Within these categories, populations were then grouped based on strength of correlation. The TUG proved to have strong correlations with outcomes utilized in the populations including individuals diagnosed with SCI, stroke, CP, and DS. In patients with SCI the TUG demonstrated a strong correlation [63,75,91] when compared with Berg Balance Scale (BBS) and timed walking tests. The BBS, Dynamic Gait Index (DGI), Figure 8 test, and timed walking tests also have strong correlations with the TUG when assessed in patients with a stroke [39,41,54,69,70,90].

There was a moderate to strong correlation between the TUG and outcomes used to assess children with CP and DS, and individuals with MS. Correlation in concurrent validity in children with CP was shown between the TUG and outcome measures such as the Five Time Sit to Stand (FTSSS), BBS, and Four-Square Step Test (FSST) [25,33,36,45,60,94]. The children with DS that were assessed show moderate to strong correlation for concurrent validity with outcome measures assessing similar activities [7,25,71]. Moderate to strong correlations to the TUG occurred in individuals with MS when compared to timed walking tests, DGI, and other mobility measures, demonstrating acceptable clinical utility to the TUG in individuals with MS [43,72,83]. The concurrent validity values vary from weak to strong correlation in outcome measures used to evaluate individuals with PD [58,80,91]. In typical

adults, depending on the outcome measure that the TUG was being compared, the correlations ranged from weak to strong as well [5,23,24,29,34,37,47,48,74,78,79,84,97].

Correlations between disease specific outcome measures demonstrated weak correlation. The Unified Huntington's Disease Rating Scale (UHDRS) was the outcome measure used to assess concurrent validity of the TUG and demonstrated weak correlation [31]. The TUG had a weak concurrent validity correlation when compared with the Lower Extremity Motor Score (LEMS) when assessed in patients with spinal cord injury [21]. The outcome measures used to assess typical children were found to have weak correlations with the TUG [57]. Table 4 expresses concurrent validity in all populations.

Predictive validity was found with area under the curve (AUC) and odds ratio in a limited number of studies, only pertaining to the typical adult population. In the first study the odds ratio data were results of multivariate logistic regression on functional mobility and balance outcomes discriminating fallers and recurrent fallers. The odds ratio reported for one or more falls was 0.77 and for two or more falls was 1.21 [24]. The second study determined if a patient takes longer than 11 s to complete the TUG, then a odds ratio of fall risk was determined to be 13.1 [97]. However, based on likelihood ratios, the optimal cut of time for determining fall risk is 12.3 s to optimize both sensitivity and specificity [97]. Lastly, AUC was reported in one study as 0.63 (95% CI; 0.57–0.69) for patients who fell in the twelve month period that the study included. The AUC slightly increased to 0.64 (95% CI, 0.58–0.70) when patients were not receiving conventional therapy. These results indicate the TUG is a potential predictor of risk for recurrent falling [78].

Discussion

The goal of the present review was to present a comprehensive overview of the ability of the TUG to be used for multiple pathologies and typical individuals. The discrepancies between

populations can frequently be attributed to differences in impairments associated with specific health conditions.

The cause of variance found in reliability and validity are due to common themes across an array of populations. For example, age impacted the performance of individuals; older individuals required increased time to complete the TUG compared to younger individuals [29,33,67,86,92]. Another common theme that impacted TUG scores was the use of multiple trials. Participants generally did better on the second trial than the first, as experience allowed for increased learning and improved performance [68]. However, if fatigue was a factor that impacted the individual, the score in latter trials may not be representative of function. Another common theme across a variety of populations is the minimal differences in inter-rater reliability. This could possibly be explained by the objectivity of the TUG. The TUG does not require advanced interpretation of results, as the only data recorded was the time taken to complete 3 meters.

Alterations in reliability and validity in the studies that examine children may have external factors that could impact the data. For example, as noted by Williams et al. when children perform the TUG they are more likely to add different movement patterns such as hopping or skipping [94]. It was recommended to redo the trial if the patient deviates from walking since this could mask the child's true ability. This data could be extrapolated to additional populations that assessed children such as DS and CP. Children may also have limited understanding of the exact directions which may lead to increased time to complete the outcome measure.

For many conditions, the level of an individual's function may affect reliability and validity. Most of these disorders they are categorized based on functional differences. The conditions that emphasize this idea include CP with Gross Motor Functional Classification Scale (GMFCS) levels, HD with United Huntington's Disease Rating Scale (UHDRS) levels, PD with Hoehn Yahr stages, SCI level of injury, and location of stroke. In addition to being classified based on functional level, there is a likely functional decline associated with these disorders. Therefore, consideration must be taken when interpreting the results of the TUG because it does not indicate the extent of injury and it is not sensitive to the individual body structure and function [91]. The TUG may have demonstrated better reliability and validity if it were consistently assessed in similar classifications of the disease within each population.

An individual may lack a specific body structure and function component due to their specific disease-causing difficulty and increased time to complete the TUG. For example, a patient may have limited functional strength to perform a sit to stand transfer but may be able to ambulate once standing. The TUG is a multidimensional test; consequently, the therapist must consider the impact of the patients' overall performance because they may be challenged by one aspect while having success with another. However, this is not reflected in the final time since the TUG is a composite time of multiple tasks performed as a whole.

Concurrent validity was assessed by comparing the TUG to another outcome measure. Outcome measures used for comparison assessed constructs in multiple domains such as: activity, participation and body structure and function. Depending on the construct being assessed, correlations ranged from weak to strong. Validity proved to be strong when the TUG was associated with outcome measures that analyze the same construct of activity. This would be expected due to the similarity in tasks being measured. For example, in patients with SCI there was a strong correlation with BBS and the timed walking test. These outcome

measures also study the same fundamental principles as the TUG such as balance and ambulation capabilities. This is also true for the outcomes used for concurrent validity with children diagnosed with CP. For this population they assessed dynamic balance and movement.

The TUG was not highly correlated with outcome measures that did not assess the same constructs as the TUG. Many studies proved this when using outcome measures that assessed alternative constructs like body structure function. In studies that assessed the individuals with HD, concurrent validity was assessed with the UHDRS. While there are components to this measure that are in line with the goals of the TUG many of the constructs fall outside the realm of activity and into body structure function categories. This is also true for the UPDRS in individuals with PD and the Lower Extremity Motor Scale (LEMS) in individuals with SCI. These differences are also noted in the studies assessing validity in typical adults. In addition, assessing specific characteristics of movement, as some studies did, would not correlate well with a test such as the TUG since it is focused on more global function.

Within each population there are population specific aspects that may account for differences in reliability and validity. First, for patients with PD there may be differences due to the on:off periods of their medication. These on:off periods of the medications can hinder or bolster their performance and should be taken into consideration when designing studies [88]. In the children diagnosed with DS there was a variety of results. According to Villamonte et al. [93], which recorded poor reliability of the TUG, the results of the study may not be able to be generalized to the population due to small sample size and the wide range of cognitive and motor abilities of the tested children.

There are various factors affecting individuals after surviving a stroke including residual effects [30,41,42,49,58,69,70,90], cognitive and psychologic changes [30,42,79], and the use of an assistive device [39] that can alter the correlation. The residual cognitive and physical changes are not the same for each person dependent upon severity and location of the stroke therefore the factors can create different barriers for each individual [30,41,42,49,58,69,70,79,90]. The use of an assistive device may alter the correlation because other outcome measures may not allow the use of an assistive device so they may demonstrate decreased performance on these measures. These functional barriers may or may not impact the mobility aspects that the TUG assesses so it is important to note the patients' specific limitations.

The construct validity could have been skewed due to decreased mental function impacting the ability to follow specific directions, maintain attention to complete a task, or ability to correctly sequence events [28,36]. Populations that typically have alterations in cognition that could cause this limitation include individuals with a stroke, children with DS or CP, and individuals with PD. Therefore, if the patient loses attention or forgets where they are going, time on the TUG may be increased and cause misrepresentation of their functional ability.

Overall, the results reflected data similar to individual systematic reviews on specific populations. The systematic reviews that assessed reliability and validity of the TUG in individuals with a stroke, SCI, or CP, all reported high values for the TUG, which is congruent with these findings [6,7,9]. The authors of the present review found conflicting evidence in the elderly population when comparing results assessing the utilization of the TUG as a fall risk predictor to previously published data [98]. The Rydwick et al. [98] review states that "... the TUG should not be used to discriminate between persons with high and low fall risk..." In comparison,

this systematic review found excellent reliability and validity in this population. The discrepancy may be due to the alternative focus on the predictive value of the TUG, while that was not the focal point of the current review. The focus of this review is to create a more comprehensive analysis for a variety of populations.

There were common strengths and weaknesses in the methodology of the included articles in this systematic review. A strength across many studies was that there were high sample sizes allowing for accurate representation of the specified population. The overall low risk of bias of each study indicated that they were sound in their methodological process. A weakness of the studies included could be attributed to study design due to many studies not using control groups to further validate their data.

There are multiple limitations to this systematic review. In relation to reliability limitations, minimal data were reported on inter-rater reliability compared to intra-rater and test-retest reliability. The TUG is an objective measure with specific instructions, and does not require advanced clinical experience, which could attribute to overall high reliability values. More limitations were noted in validity studies; one such limitation was in regard to the outcome measure of comparison. Many of the included studies used disease specific outcome measures that did not assess the same constructs. If they did not assess similar constructs, then validity data was misleading.

The predictive validity studies only assessed typical adults or children. A similar limitation was found in the lack of normative data on specific diagnoses and in typical individuals aged 9 to 38. An increase in research on normative data across all populations would allow for more research on predictive validity.

Another limitation included gaps within the literature for many populations. These gaps show a need for future research regarding the TUG in populations other than the individuals who are frail and elderly. This was evidenced by the lack of normative data for a variety of age groups such as 20–60 year olds who may also experience CNS insults or neurodegenerative diseases. In addition, this could be a useful tool for adolescence and adults in individuals with developmental disorders, such as CP and DS but no comparison of normative data exists. The increase in normative data would allow for more predictive validity, which could help develop the true clinical utility of the TUG across a patient's lifespan. Limitations in this systematic review's methodology include a risk for missing relevant articles or error in data extraction. Another limitation is a low kappa agreement between reviewers in regards to final inclusion. This low kappa value is due to being chance corrected, the present review examined many articles when determining inclusion and therefore had high agreement with certain categories that the kappa calculated determined was by chance.

Overall, the TUG is determined to have excellent reliability across all analyzed populations. In comparison, concurrent validity values had a broader range of results. This could be because the TUG shows stronger correlations with other dynamic balance tests rather than outcome measures assessing different aspects of function. When being compared to other activity focused outcome measures, in any population under study, the TUG proved to have high concurrent validity. The results of this systematic review indicate that the clinical utility of the TUG is useful across the continuum of care when assessing many populations, regardless of age.

Disclosure statement
